ABSTRACT

OBJECTIVE: To determine the frequency of vaginal septum and other causes of infertility using MRI based endovaginal gel instillation technique. METHODS: A retrospective, cross-sectional study was performed on 50 infertile patients who had a strong clinical suspicion of vaginal septum based on history and clinical examination comprising bimanual gynecological examination and speculosity. MRI was performed on these 50 patients and 08 patients who were diagnosed as vaginal septum were subjected to endovaginal gel instillation technique in order to diagnose its obstructed or non-obstructed type. The data was collected over a period of 01 year; from 01st January 2017 to 31st December 2017. The study center was the Department of Radiology, at Liaquat National Hospital, Karachi. RESULTS: Out of these 50 infertile patients which were under 40 years, 16 patients (32%) had hydroasplinx, 8 patients (16%) had hemorrhagic cyst, 7 patients (14%) had endometriotic cyst, 5 patients (10%) had hematocolpos, 4 patients (8%) had bicornuate uterus, 2 patients (4%) had OHVIRA syndrome. Only 08 patients (16%) had vaginal septum out of which 4 patients (8%) had obstructed while 4 patients (8%) had non-obstructed vaginal septum diagnosed on endovaginal gel instillation technique. CONCLUSION: The MRI imaging gel instillation technique shown by our single center study is considered to be a useful, beneficial and minimally invasive approach for diagnosing obstructed and non-obstructed vaginal septum. We also believe that this method will be recognized as a superior diagnostic approach in patients suffering from vaginal endometriosis and thus help the gynecologists in planning effective therapeutic strategies. Keywords: Endovaginal gel instillation, MRI scan

Introduction

MRI is superior in demonstrating tissue contrast in congenital Mullerian anomalies, however, it may be difficult to distinguish vaginal borders owing to the normally collapsed vaginal walls. Instilling a contrast medium can adequately expand and fill the vagina, thus enhancing the visualization of vaginal anatomy and pathology. This technique provides an objective and reproducible way of measuring the level and thickness of a vaginal septum. This is important information preoperatively, as it will determine the route of operation (perineal or combined approach) and the need for using bowel mucosa or skin to line a large vaginal defect.1,2,3

MRI has gained ground in the evaluation of vaginal diseases due to its increasing availability and technological developments, which has allowed the development of faster and better quality protocols. Such protocols characterize the vaginal anatomy in detail, as well as its relationship with pelvic structures, besides allowing for a dynamic study during Valsalva maneuver, in the clinical suspicion of perineal descent. Additionally, diffusion and perfusion techniques have
the potential to provide functional data to the traditional anatomical study. The imaging protocol included a T1-weighted (W) turbo spin-echo (TSE), a T2-W TSE, a T1-W TSE fat-saturation, performed in the transverse plane (perpendicular to axis of cervix). A T2-W TSE sequences and a T1-W TSE fat-saturation were performed on sagittal plane. The transverse and sagittal T2-W TSE and the transverse and sagittal T1-W TSE fat-saturation sequences were performed before and after the introduction of ultrasonographic gel into the vaginal canal. No intravenous contrast medium was administered.

There is no consensus in the literature regarding use of vaginal contrast. Therefore, the use of vaginal contrast remains optional. Vaginal gel is useful for the evaluation of cervical cancer patients, especially in the subgroup who do not undergo evaluation under anesthesia. About 20-30 ml of warm ultrasound gel is placed in the vagina after positioning the patient on the table. Usually, vaginal contrast is well tolerated and does not cause any significant discomfort. Vaginal opacification with gel provides high signal intensity on T2W images and enables excellent definition of vaginal fornices and cervix, allowing for accurate assessment of vaginal involvement, especially in tumors with an exophytic cervical component.5,6,7

The vaginal walls are normally collapsed and therefore difficult to evaluate. There are some difficulties in adequate visualization of fibro-fatty components of vaginal septum. Therefore, vaginal distension by opacification with ultrasound gel could help to delineate the cervix, vaginal fornices and hence is a helpful tool in not only detecting vaginal septum but also in diagnosing endometriosis.8

Material and Methods

A retrospective, cross-sectional study was performed on 50 infertile patients who had a strong clinical suspicion of vaginal septum based on history and clinical examination comprising bimanual gynecological examination and speculum examination. MRI was performed on these 50 patients and 08 patients who were diagnosed as vaginal septum were subjected to endovaginal gel instillation technique in order to diagnose its obstructed or non-obstructed type.

Consent was obtained from these patients. Patient lies in supine position with knees flexed, legs abducted. The aseptic technique includes usage of a vaginal speculum and the area was cleaned and sterilized with chlorhexidine. The operator uses 30 - 40 ml of water based aqueous gel (Aquasonic® 100 - ultrasound transmission gel) in 50 cc syringe, which is injected into the vaginal cavity resulting in its adequate distension. Care was taken to expel all air bubbles from the syringe during gel instillation. T2 weighted images were taken in sagittal and coronal planes. The data was collected over a period of 01 year; from 01 January 2017 to 31 December 2017. The study center was the Department of Radiology, at Liaquat National Hospital, Karachi. Approval of the Ethical Review Committee of the institution was obtained before the data collection. Full confidentiality of patients was maintained. All examinations were performed on a 1.5 Tesla MRI scanner (Toshiba

Results

Out of these 50 infertile patients which were under 40 years, 16 patients (32%) had hydrosalpinx, 8 patients (16%) had hemorrhagic cyst, 7 patients (14%) had endometriotic cyst, 5 patients (10%) had hematocolpos, 4 patients (8%) had bicornuate uterus, 2 patients (4%) had OHVIRA syndrome. Only 08 patients (16%) had vaginal septum out of which 4 patients (8%) had obstructed while 4 patients (8%) had non-obstructed vaginal septum diagnosed on endovaginal gel instillation technique (Tab. 1 and Fig. 1a).

Discussion

The prevalence of Mullerian duct anomalies, although rare, ranges from 0.001% to 10% in general population and 8 - 10% in women with an adverse reproductive history. Among these anomalies, imperforate hymen is the most common anomaly with an incidence of 1/1,000 to 1/10,000. Transverse vaginal septum (TVS) with a prevalence of 1 in 30,000 to 1 in 80,000 women is rarer than imperforate hymen. Both obstructive vaginal malformations may be asymptomatic in childhood. Most of the cases become symptomatic after menarche.9,10 Transverse vaginal septum results from incomplete fusion between the vaginal components of the mullerian ducts and the urogenital sinus. A transverse vaginal septum divides the vagina into two segments, reducing its functional length and in most situations resulting in outlet tract obstruction. These septa are located in the upper vagina in 45% of cases but can
also be located in the mid (40%) or lower (14%) vagina. Clinical presentation depends on whether it is complete or partial. With complete septum, the menstrual blood accumulates in the genital tract resulting in hematoocolpos and hematometra. Such patients usually present with cyclic lower abdominal pain and occasionally lower abdominal mass (hematometra) may be palpable. Incomplete septum may manifest later in life, allows partial egress of menstrual blood and such patients complain of dysmenorrhea and dyspareunia. Clinical examination of the vulva will yield normal findings if the septum is in the mid or upper vagina, but a valsava maneuver will reveal a bulging vaginal membrane if the septum is in the lower vagina. MR imaging can be useful in depicting the pelvic anatomy, help determine the thickness of the vaginal septum, and aid in the selection of the appropriate surgical technique. Identification of the cervix on MR images is crucial for differentiating a high septum from congenital absence of the cervix. Longitudinal vaginal septum may occur in association with uterine anomalies, most commonly in cases of uterus didelphys. Only some of the individuals who present with a longitudinal vaginal septum will be found to have a normal uterine cavity. Many cases go unrecognized because these septa do not necessarily involve a functional disorder. Longitudinal vaginal septum is thought to develop as a consequence of either failure of fusion of the lateral mullerian ducts, resulting in duplication of the uterus, cervix (uterus didelphys), and vagina; or incomplete resorption of the vaginal septum, which may or may not be obstructive. Patients may experience difficulty with sexual intercourse or vaginal delivery. Other manifestations will depend on whether an additional anomaly (with or without obstruction) is present. Longitudinal vaginal septum alone does not have an impact on fertility rates or obstetric outcomes.

Diagnosis of vaginal septum can be confirmed either by sonography or magnetic resonance imaging (MRI). Saline contrast sonohysteroscopy (SHG) is an alternative technique in which the endometrial cavity is distended with saline during ultrasonic examination and it permits single layer evaluation of the endometrial lining and enables the sonologist to reliably distinguish focal from diffuse endometrial pathologic conditions. The transvaginal ultrasound probe is inserted in this technique and approximately 10 ml of sterile saline solution is injected slowly through the catheter under direct sonographic visualization. Multiple sagittal and coronal images are obtained. It is helpful in detection of the endometrial cavity for the presence of polyps, submucous fibroids, focal endometrial thickenings or other pathologic conditions. weighted fat saturation sequences, indicating blood plaques, was detected only after vaginal distension. An MRI with endovaginal gel allows essential preoperative mapping for the surgical removal of the DIE lesions. Furthermore, this method stands out because of higher sensitivity compared to transvaginal ultrasonography and MRI without gel, detecting more lesions. Higher subsequent pregnancy success rate has been reported with repair of a vaginal obstruction. Pregnancy success rate is increased in patients with a complete transverse vaginal septum of the lower third of the vagina as compared with those with a higher septum. This is since in patients with a higher vaginal septum, retrograde menstruation occurs early after the onset of menstruation as only a small portion of vagina is present that predisposes these patients to the development of endometriosis leading to infertility in these cases. Thus, prompt diagnosis and surgical correction to drain accumulated blood may preserve reproductive capacity by preventing this sequela. Distention of the vagina can also often aid diagnosis and staging of pelvic cancers. MRI is often used for surveillance after treatment of patients with gynecologic malignancies. After hysterectomy, the vagina is typically well delineated when gel is used. Vaginal distention improves detection of recurrence and its relationship with the vaginal cuff, and the use of gel can increase confidence in excluding recurrence. Thus administration of vaginal gel before pelvic MRI is inexpensive, well tolerated, and can improve the diagnostic usefulness of MRI for a number of benign and malignant gynecologic conditions.

**Conclusion**

The MR imaging gel instillation technique shown by our single center study is considered to be a useful, beneficial and minimally invasive approach for diagnosing obstructed and non-obstructed vaginal septum. We also believe that this method will be recognized as a superior diagnostic approach in patients suffering from vaginal endometriosis and thus help the gynecologists in planning effective therapeutic strategies.
